## Abstract

### Keywords

- ▶ primary melanocytic cerebral tumor
- ▶ management protocol
- ▶ prognosis
- ▶ systematic review

Primary melanocytic cerebral tumors form a spectrum of different lesions that range from benign to extremely malignant, such as an intracranial melanoma. This article points out some characteristics of primary melanocytic cerebral tumors and discusses their management and prognosis, based on a systematic literature review and a case of primary cerebral malignant melanoma.

Because the biological characteristics of primary melanocytic cerebral tumors remain unclear, it appears that total surgical resection of the tumor followed by oncologic treatment is the mainstay of the management. The prognosis still depends on the degree of malignancy.

## Introduction

Primary melanocytic lesions of the central nervous system represent a set of various entities ranging from benign to highly malignant. These lesions include diffuse melanocytosis, melanocytoma, meningeal melanomatosis, and malignant melanoma.<sup>1</sup>

Contrary to metastatic melanoma, which is the third most frequent tumor metastasizing to the brain,<sup>2</sup> primary melanocytic cerebral tumors are scarce, originating from melanocytes within the leptomeninges, which are pigment-producing cells of neural crest origin.<sup>3,4</sup> In certain circumstances, these cells may assume neoplastic patterns.

Distinctive diagnostic tools are helpful in searching the source of the tumor and defining its biological performance. Accordingly, a variety of imaging modalities and pathohistologic techniques may be used to define the dignity of these considerably diverse lesions. However, the management for

the entire spectrum of such lesions are the same, consisting of gross tumor resection and oncologic treatment. Nonetheless, it seems that the prognosis is highly dependent on the degree of malignancy.

This article describes clinical, imaging, and pathohistologic features of primary melanocytic cerebral tumors, and discusses management strategies and prognosis, based on a systematic literature review and a case illustration of primary cerebral malignant melanoma.

## Case Illustration

The presenting symptom of a 59-year-old man was right-side homonymous hemianopsia along with a headache. A computerized tomography (CT) of the brain with contrast enhancement and T1/T2-weighted magnetic resonance imaging (MRI) showed a parasagittal consistent mass lesion of the left occipital lobe with no meningeal dissemination. (▶ **Figs. 1** and **2A, B**) A clinical, dermatologic and ophthalmologic examination

ISSN 2193-6315.

**Fig. 1** Preoperative contrast-enhanced axial computerized tomography (CT) scan demonstrated a well-defined supratentorial homogeneous mass lesion located parasagittally in the left occipital lobe with peritumoral edema and no leptomeningeal involvement.

ruled out the existence of extracranial, cutaneous, and/or chorioretinal melanoma.

The patient underwent a left-side occipital osteoplastic craniotomy and the tumor was removed. Light microscopy of tissue samples disclosed a pathohistologic feature similar to melanoma with highly cellular anaplastic tissue consisting of polymorphic, partly epithelioid, and spindle atypical melanocytes with hyperchromatic nuclei and sporadic mitoses (► **Fig. 3A, B**). Immunohistochemistry confirmed that the cells are diffusely positive for Melan A (► **Fig. 4A**), S-100 protein (► **Fig. 4B**), and vimentin, focally positive for Human Melanoma Black (HMB-45) antibody, and negative for glial fibrillary acidic protein (GFAP), epithelial membrane antigen (EMA), and pancytokeratin. Melanin pigment was detected in the tumor tissue.

The pathohistologic findings, together with the negative dermatologic and ophthalmologic examinations, suggested a primary cerebral melanoma.

Postoperative control contrast-enhanced axial CT showed no remaining tumor, and the patient's recovery was complete. At a 1-year clinical and neuroradiologic follow-up, the patient was without signs of recurrent disease.

## Review of the Literature

Medline literature database was selected for the search. The search time frame was set from January 1983 to January 2013. All studies describing the treatment of central nervous system melanocytic lesions, irrespective of language, publication status and level of evidence, were included in the preliminary analysis. Then, articles describing secondary or spinal disease were excluded, leaving the articles describing the treatment

**Fig. 2** (A) Preoperative T1-weighted axial magnetic resonance imaging (MRI) showed a well-delineated hyperintense, intensively contrast-enhancing tumor adjacent to the superior sagittal sinus and with a compressive effect onto surrounding brain parenchyma resembling a meningioma or a melanin-infested tumor. (B) Preoperative T2-weighted MRI revealed a homogeneous hypointense tumor localized in the left occipital lobe.

of primary central nervous system melanocytic lesions. Two of the authors analyzed the search results independently.

The preliminary search yielded 129 results. Based on title, abstract, and keywords, 38 articles were selected as potentially relevant, and these were obtained in a full text. After excluding intracranial secondary neoplasm and spinal localization of the disease, 14 articles remained for further analysis<sup>3,5-17</sup> (► **Table 1**),

The following data were extracted: age, sex, treatment (surgery, irradiation, chemotherapy), pathohistologic diagnosis, and outcome.

**Fig. 3** (A) Light microscopic pathohistologic analysis (original magnification  $\times 400$ ; hematoxylin-eosin stain) showed anaplastic tumor cells (atypical melanocytes) with a spindle cell appearance, pleomorphic nuclei, and typical mitotic forms. (B) Light microscopic pathohistologic analysis (original magnification  $\times 400$ ; hematoxylin-eosin stain) depicted polymorphic variably pigmented, cytologically atypical melanocytic tumor cells arranged in loose nests.

A total of 37 patients from 14 studies were found. The median age was 36 years (range: 11–74 years). There were 20 male and 17 female patients. Pathohistologic diagnosis was melanoma in 26 patients, intermediate-grade melanocytoma in 3 patients, melanocytoma in 7 patients, and meningeal melanomatosis in 1 patient. All patients were surgically treated. Total resection was achieved in 23, subtotal resection in 10 patients, and 4 patients had tumor biopsy only. Twelve patients received radiotherapy, with doses ranging from 20 Gy to 60 Gy. Chemotherapy was performed in 3 patients. The combination of procarbazine, lomustine, and vincristine; nimustine, teniposide, temozolomide; and cis-platinum, dacarbazine, and bischloronitrosourea with carmustine, was applied in 1 patient each. The median disease-free survival was 20 months for patients with melanocytoma, and 13 months for patients with melanoma. **►Table 1** summarizes the data.

## Discussion

No current evidence-based guidelines for diagnosis and management of primary cerebral melanocytic tumors exist.

**Fig. 4** (A) Immunohistochemistry (original magnification  $\times 400$ ; Melan A) revealed that tumor cells were diffusely positive for Melan A protein. (B) Immunohistochemistry (original magnification  $\times 400$ ; S-100) showed that tumor cells were expressing S-100 protein.

Therefore, we performed a systematic review of the literature that predominantly identified case reports and small case series (**►Table 1**).

There are several diverse types of cerebral melanocytic tumors including meningeal melanomatosis, melanocytoma, and primary malignant melanoma that is extremely rare and lacking any correlation with family history, sun-initiated skin damage, or precursor nevi. The dignity of these tumors varies considerably.

A variety of these tumors may present as solid intra- or extraaxial mass lesions with or without leptomeningeal extent.<sup>3</sup> The clinical signs and symptoms are usually similar to those of other intracranial tumors, most frequently consisting of intracranial hypertension and focal neurologic deficit; our patient presented with homonymous hemianopsia. It is impossible to differentiate the different types of primary cerebral melanocytic tumor, and to estimate its dignity by neuroradiologic diagnostics only. To eliminate an extracerebral primary lesion, as well as a metastatic tumor, a meticulous clinical examination of the skin and eyes is necessary.<sup>18</sup>

Distinctive pathohistologic aspects are supportive in determining the tumor origin and in assessing its biological characteristics.<sup>17</sup> Pigmented tumor cells arranged in tight

sheets encompassing regular nuclei together with the absence of mitotic activity are typical for melanocytoma.<sup>19</sup> Cerebral malignant melanoma is often suspected when cytologically atypical and mitotically active melanin-pigmented pleomorphic cells, rising in loose-fitting shells encircling eosinophilic hyperchromatic nuclei, are found (►Fig. 2A, B). Moreover, immunoreactivity indicates expression of melanocytic marker proteins (S-100, Melan A, and HMB-45) (►Figs. 2A, B and 3A, B). In our patient, the diagnosis of a malignant cerebral melanoma was made.

According to the literature review, a complete tumor resection appears as the best treatment modality and is highly associated with a better prognosis. Because the biological behavior of a primary cerebral melanoma is unpredictable and recurrence may occur following incomplete resection, some authors also suggest postoperative whole brain radiation therapy to improve the outcome.<sup>9</sup> Regarding the prognosis, the data in the literature are inconsistent, which prevents well-reasoned conclusions. However, some authors assume a better long-term outcome of primary melanocytic cerebral tumors in comparison with metastatic melanoma.<sup>3</sup> Others even reported a 12-year survival after the diagnosis of primary malignant melanoma.<sup>3,20,21</sup> Regardless of the tumor dignity, radical tumor resection is the mainstay of the management.

Radiotherapy, chemotherapy, and immunotherapy may be considered as nonsurgical options, but their efficacy is not yet proven.<sup>3</sup>

## Conclusion

Reviewing the literature, it seems that the prognosis of primary cerebral melanocytic tumors remains highly dependent on their dignity with more malignant lesions having a poorer outcome. Complete surgical resection, if possible, seems to be the main treatment option.
